A Bayesian Approach for Active Fault Isolation with an Application to Leakage Localization in Water Distribution Networks

Gert van Lagen, Edo Abraham, and Peyman Mohajerin Esfahani

Abstract—This paper proposes an active fault isolation method for application to water distribution networks (WDNs) in order to localize leaks. The method relies on the classification of observed outputs to a discrete set of hypothetical faults. Due to parametric uncertainties, the outputs are random vectors that follow unknown probability distribution functions (PDFs). The output PDFs corresponding with the considered faults are approximated using smooth kernel density estimation (SKDE). They are used to calculate the posterior probability of each hypothesis, given the observed outputs, by applying Bayes' rule. The difficulty to classify observed outputs to the right fault comes from the overlap between output PDFs. An active algorithm is introduced that proactively minimizes the joint overlap between the output PDFs by designing optimal control inputs. Due to physical limitations on control inputs and depending on the intensity of uncertainties, full separation, and hence fault isolation, cannot be guaranteed for a single observed output. Therefore subsequent observations are used in an iterative framework, where the posterior probabilities of the previous time step serve as the prior probabilities for the next time step. The method is applied to locate leaks in a benchmark WDN for different levels of uncertainty in customer water demand and leakage magnitude. Improvements in performance are observed in comparison to the best considered passive method from literature.

I. INTRODUCTION

ONE of the main challenges for water utilities is the diagnosis and control of leakage from ageing water distribution networks (WDNs). The early detection and management of leaks, in addition to reducing cost in non-revenue water and conserving energy, is critical to mitigate deterioration of pipes and surrounding infrastructure. Water loss due to leakage varies between 5 and above 50 per cent of the supplied volume, respectively, for well managed and older poorly maintained networks [1]. Leakage reduction beyond the economically optimal level of about 15 per cent [2] is further motivated by stringent regulations and imminent risks. One risk is a poorer water quality due to temporarily negative pressures that allow intrusion of pollutants into the network, potentially jeopardising public health [3]. A further threat is that very

small leaks can gradually grow in size, eventually into pipe bursts, which can render (a part of) the network inoperable and result in damage to other infrastructure and also economical losses due to flooded areas. Leaks are also known to cause destructive and dangerous sink holes due to underground soil erosion [4]. Finally, reducing the annual global loss of 32 billion m^3 of potable water [5] will help alleviate the water stress caused by the mutually reinforcing global issues of rapid urbanization and increasing water scarcity.

Leakage analysis includes the fault diagnosis tasks of detection, isolation, identification and estimation. These techniques respectively involve the determination of whether or not a leak is present, if so, to estimate its location, type and magnitude [6]. This paper focuses on leak localization techniques.

Different methods to locate leaks in WDNs have been proposed in literature. Conventional deterministic techniques include random and regular sounding surveys using listening sticks and acoustic loggers, and step-testing of district metered areas (DMAs) through gradual valve closures [7]. DMAs are sub-systems that can be analytically isolated through segregation of the WDN by means of (dynamic) boundary valves and metering the flows at remaining open connections [8], [9]. More advanced deterministic methods like leak noise correlators, pig-mounted acoustic sensing and gas-injection techniques [10] are the most precise at locating leaks. However all these techniques come with expensive equipment cost and are man-hour intensive, and so are not scalable. In addition, the suppression of leakage sound signatures by reduced pressures in active pressure management has also made these methods of limited application [7], [10].

To make those deterministic methods scalable, recent approaches use model-based analysis to reduce the search space. These methods use near real-time telemetry data from pressure sensors and flow metres distributed over the network and rely on a calibrated predictive hydraulic model. Based on observed residuals that reflect how pressure measurements from the leaky reality deviate from predicted pressure values in the absence of leakage, their aim is to designate a leak location from a discretized set of possibilities through comparison to offline generated residual signatures corresponding to the possible locations [11]. Recent developments toward this problem apply machine learning techniques like k-nearest neighbours, neuro-fuzzy [12], Bayesian classifiers [13] as well as Fisher discriminant analysis [14] and Dempster–Shafer [15] to classify observed residuals to one of the possible leak locations, which have shown best results when applied over multiple

time steps. Recently, there are also some progress to leverage these tools to go beyond the problem of detection in order to answer more complex questions such as estimating the time and intensity of the leakage [16], [17]. Similarly, [18] makes use of time-series analysis for detecting the start time static and growing leaks, and then model-based passive approaches for leak localisation.

The difficulty to classify observed residuals to one of the possible leak locations comes from the overlap between corresponding residual sets due to uncertainties, such that leak isolation cannot be achieved under all possible observed residuals. All these techniques in literature rely on nominal input-output data from the network, i.e. control input strategies are not adapted to improve leak localization, which we refer to as passive fault diagnosis (PFD) methods. As the joint overlap in residual space increases with growing uncertainties, these PFD methods are of limited application. Therefore in this work we present a novel active fault diagnosis (AFD) algorithm for faster and more reliable leak isolation. Where pressure control inputs are usually regulated at a minimum level using pressure regulating valves (PRVs) [9], we show that they can also be optimized to enhance active leakage isolation [19]. We will make use of output observations directly, rather than the common residual observations used in literature that subtract two random 'output' variables, because composed random variables gain a higher joint spread and hence, unnecessarily, stochastically deteriorate the observed samples. We also introduce new control design strategies for pressure inputs that minimize the probability of misisolation, i.e. the overlap between output sets corresponding with considered leak locations. The output sets are described by probability distributions, which are estimated by means of smooth kernel density estimation (SKDE) [20] through extrapolation of output realizations from Monte Carlo simulations. Due to physical limitations and regulatory constraints, the pressure control inputs to the network are bounded. Hence it is plausible that output sets cannot be fully separated, such that isolation is not guaranteed. However, by iteratively applying Bayes' rule over consecutive time steps, leak isolation can be improved in terms of reliability and speed compared to the PFD methods in [12]–[14]. At nighttime, when user demand is low [21], the proposed AFD algorithm is applied to a benchmark network for different degrees of uncertainty. Its performance is compared to that of the best considered PFD method proposed in [13] with the slight adaptation of using the output space instead of the residual space.

The paper is structured as follows. In Section II the active fault isolation problem is stated and a motivating example for leak localization in a WDN is given. In Section III-A, an AFD algorithm is proposed that solves the stated problem and is directly applicable to locating leaks in a WDN, which is further elaborated in Section IV. In Section V, simulation experiments are presented with a benchmark WDN as a case study, in which the AFD algorithm is tested for different leak scenarios and compared against a PFD method. Finally, conclusions are drawn and recommendations for future work are given in Section VI.

II. PROBLEM STATEMENT AND MOTIVATING EXAMPLE

In this section a class of models describing the steady state of a non-linear system subject to possible faults is introduced. Consider the set of algebraic equations

$$\text{Model}: \begin{cases} F(\boldsymbol{x}, \boldsymbol{u}, \boldsymbol{d}, K) = 0 \\ \boldsymbol{y} = C(\boldsymbol{x}), \end{cases} \tag{1}$$

where the function F models the steady state of the system, the signal $\boldsymbol{x}$ denotes the state of the system, $\boldsymbol{u}$ is the control input, $\boldsymbol{d}$ denotes the natural disturbances that the system may encounter, and $\boldsymbol{y}$ is the available measurement signal. We highlight that the bold signals $\boldsymbol{x}, \boldsymbol{u}, \boldsymbol{d}, \boldsymbol{y}$ are time-varying and take vector values from $\mathbb{R}^{n_x}, \mathbb{R}^{n_u}, \mathbb{R}^{n_d}, \mathbb{R}^{n_y}$, respectively. The parameter $K = [K_1, \ldots, K_{n_K}] \in \mathbb{R}^{n_K}$ is a constant vector representing n_K different possible faults, i.e., when the ith component of K is non-zero (i.e., $K_i \neq 0$), then the system is in the ith faulty mode.

The set of algebraic equations (1) essentially describes the input-output mapping between the variables $(\boldsymbol{d}, \boldsymbol{u}; K)$ and $\boldsymbol{y}$. In this view, the output can be explicitly described by $\boldsymbol{y}(\boldsymbol{d}, \boldsymbol{u}; K)$. For brevity, and with slight abuse of notation, we may use the shorthand notation

$$\boldsymbol{y}^{[i]} := \boldsymbol{y}(\boldsymbol{d}, \boldsymbol{u}; K_i), \qquad i \in \{1, \cdots, n_K\}$$

where $\boldsymbol{y}^{[i]}$ denotes the output of the system (1) in the presence of the fault i, namely, when the only component of the vector K that is *not* zero is K_i. In this study we treat $(\boldsymbol{d}; K_i)$ as random variables whose behavior follows a certain distribution from which we have access to historical data or sample realizations. We also reserve the symbol "$\widehat{}$" for sample realizations of the random variables, e.g., given realizations $(\widehat{\boldsymbol{d}}, \widehat{K}_i)$, we denote an output realization $\widehat{\boldsymbol{y}}^{[i]} = \boldsymbol{y}(\widehat{\boldsymbol{d}}, \boldsymbol{u}; \widehat{K}_i)$. The aim of this study is to address the following objective.

Problem 1 (Active fault isolation). *Consider the system* (1) *under a single fault i^*, i.e., $K_j = 0$ if and only if $j \neq i^*$. Given the measurement signal $\boldsymbol{y}$ and statistical information of the natural disturbance $\boldsymbol{d}$, synthesize a sequence of input signal $\boldsymbol{u}$ as well as a diagnosis rule in order to maximize the probability of identifying the fault type i^*.*

The relevance of Problem 1 is endorsed by the following motivating example.

Example 1 (Leak localization in water distribution network). *Water enters a WDN at n_u inlets and is supplied to consumers abstracted by n_K nodes that are connected to the inlets through a network of n_p pipes. The steady state of a WDN can be described by a model of the form in* (1)*, where the state $\boldsymbol{x} := \begin{bmatrix} \boldsymbol{q} & \boldsymbol{h} \end{bmatrix}^T \in \mathbb{R}^{n_x}$ consists of the flows $\boldsymbol{q} \in \mathbb{R}^{n_p}$ through the pipes (in m^3/s) and the hydraulic heads $\boldsymbol{h} \in \mathbb{R}^{n_K}$ at the nodes (in mH_2O). The control inputs $\boldsymbol{u}$ are the inlet pressures of the network, which are regulated using PRVs. The nodal consumer demands act like natural disturbances $\boldsymbol{d}$ on the network and need to be predicted using statistical information. The output of the network consists of the measured part of the system's state, where usually $n_y \ll n_x$. Consider the WDN under the presence of a single leak i^* at one of*

the n_K nodes, then, active isolation of this fault parametrised by K involves the synthesis of a sequence of control inputs $\boldsymbol{u}$ in order to maximize the probability of identifying the fault type i^* based on a sequence of measurements $\boldsymbol{y}$.

III. Proposed Methodology

In this section we provide an active fault diagnosis methodology built on a Bayesian perspective, an approach in which Bayes' theorem is used to update the probability for a *hypothesis* as more *information* is revealed to us. In the context of active fault isolation, roughly speaking, the hypothesis is our current belief about the probability of occurring for each fault (i.e., $K_i \neq 0$) and the information is the output measurement $\widehat{\boldsymbol{y}}^* = \boldsymbol{y}(\widehat{\boldsymbol{d}}, \boldsymbol{u}; \widehat{K}_{i^*})$ from the actual system, which is supposed to be generated by an unknown fault mode i^*. The proposed active fault isolation in this study comprises two main steps: (i) update our belief upon receiving an output measurement $\widehat{\boldsymbol{y}}^*$, (ii) introduce an appropriate input signal $\boldsymbol{u}$.

A. Bayesian update of hypotheses probabilities

Recall that in the setting of this study we believe that the system is faulty and that one of the modes $i \in \{1, \cdots, n_K\}$ occurs. Looking at the problem from a Bayesian perspective, it is then natural to define the hypothesis set $\mathbb{H} = \{1, \cdots, n_K\}$ along with a probability distribution $\mathbb{P}$ representing our current (*prior*) belief about hypothesis candidates. Formally speaking,

$$\mathbb{P}(i) := \text{Prob}(\text{fault mode: } i), \qquad i \in \mathbb{H}. \tag{2}$$

Recall also that given an input signal $\boldsymbol{u}$, the output of the system under fault mode i, denoted by $\boldsymbol{y}^{[i]} = \boldsymbol{y}(\boldsymbol{d}, \boldsymbol{u}; K_i)$, is a random variable whose distribution is induced by the distributions of the variables $(\boldsymbol{d}; K_i)$ through the algebraic equations (1). With this in mind, we denote the (conditional) distribution of the output measurements by

$$\boldsymbol{y}^{[i]} = \boldsymbol{y}(\boldsymbol{d}, \boldsymbol{u}; K_i) \sim \mathbb{P}(\mathrm{d}y|i, \boldsymbol{u}) = p(y|i, \boldsymbol{u})\mathrm{d}y, \tag{3}$$

where $p(y|i, \boldsymbol{u})$ represents the probability density function; throughout this study we assume such a density function exists. Given the definitions in (2) and (3), the marginal density distribution of the output measurement is

$$p(y|\boldsymbol{u}) = \sum_{j=1}^{n_K} p(y|j, \boldsymbol{u})\mathbb{P}(j). \tag{4}$$

Upon receiving a realization of the output $\widehat{\boldsymbol{y}}^*$ under the input signal $\boldsymbol{u}$, one can update the prior belief concerning the hypothesis candidates in (2) by means of Bayes' theorem through the relation

$$\mathbb{P}(i|\widehat{\boldsymbol{y}}^*, \boldsymbol{u}) = \frac{p(\widehat{\boldsymbol{y}}^*|i, \boldsymbol{u})}{p(\widehat{\boldsymbol{y}}^*|\boldsymbol{u})}\mathbb{P}(i) = \frac{p(\widehat{\boldsymbol{y}}^*|i, \boldsymbol{u})\mathbb{P}(i)}{\sum_{j=1}^{n_K} p(\widehat{\boldsymbol{y}}^*|j, \boldsymbol{u})\mathbb{P}(j)}, \tag{5}$$

where the second equality follows from (4). The conditional distribution $\mathbb{P}(i|\widehat{\boldsymbol{y}}^*, \boldsymbol{u})$ in (5) is also known as the *posterior* distribution.

Approximation techniques: Given the prior distribution (2), the key ingredient is the density function $p(\widehat{\boldsymbol{y}}^*|i, \boldsymbol{u})$ evaluated at the measurement $\widehat{\boldsymbol{y}}^*$; this quantity is also known as likelihood in the statistics literature [22, Chapter 4.4]. As pointed out earlier, this density function is essentially determined by the distributions of $(\boldsymbol{d}; K_i)$ through the system equations (1). In general, the analytical description of this density is not available and one has to resort to approximation techniques for numerical purposes. For instance, for each hypothesis $i \in \mathbb{H}$, given an input signal $\boldsymbol{u}$, and M realizations $(\widehat{\boldsymbol{d}}_m, \widehat{K}_{i,m})$, $m \in \{1, \ldots, M\}$, one can simulate the system (1) and compute M output realizations $\widehat{\boldsymbol{y}}_m^{[i]}(\boldsymbol{u})$, $m \in \{1, \ldots, M\}$; note that these realizations depend on the choice of $\boldsymbol{u}$. A single realization can be obtained by fixing $\boldsymbol{u}$ and i, generating a realization of $\boldsymbol{d}$ and solving equation (1) for $\boldsymbol{y}$. Now, since the required number of realizations for all considered hypotheses scales proportional to $M \times n_K$, it becomes computationally very demanding to take a large M. Therefore, having a moderate number of output samples $\{\widehat{\boldsymbol{y}}_m^{[i]}(\boldsymbol{u})\}_{m \leq M}$, we utilize a kernel function $\kappa : \mathbb{R}^{n_y} \times \mathbb{R}^{n_y} \to \mathbb{R}_+$ to arrive at a smooth approximation of the conditional probability density distribution of $\boldsymbol{y}$ given $(i, \boldsymbol{u})$:

$$p(y|i, \boldsymbol{u}) \approx \frac{1}{M} \sum_{m=1}^{M} \kappa(y, \widehat{\boldsymbol{y}}_m^{[i]}(\boldsymbol{u})). \tag{6}$$

Considering the approximation scheme (6), the approximation of the posterior distribution (5) then reduces to

$$\mathbb{P}(i|\widehat{\boldsymbol{y}}^*, \boldsymbol{u}) \approx \frac{\sum_{m=1}^{M} \kappa(\widehat{\boldsymbol{y}}^*, \widehat{\boldsymbol{y}}_m^{[i]}(\boldsymbol{u}))\mathbb{P}(i)}{\sum_{j=1}^{n_K} \sum_{m=1}^{M} \kappa(\widehat{\boldsymbol{y}}^*, \widehat{\boldsymbol{y}}_m^{[j]}(\boldsymbol{u}))\mathbb{P}(j)}$$

In the next section, we will provide a specific example of such kernels. Note that when the prior probability $\mathbb{P}(i) = 0$, then the posterior update (5) remains $\mathbb{P}(i|\widehat{\boldsymbol{y}}^*, \boldsymbol{u}) = 0$ irrespective of the observation $\widehat{\boldsymbol{y}}^*$. In this light, another approximation idea to practically improve the efficiency of the Bayesian update rule (5) is to introduce a threshold, say ζ, and set the posterior probability $\mathbb{P}(i|\widehat{\boldsymbol{y}}^*, \boldsymbol{u})$ to zero if $\mathbb{P}(i|\widehat{\boldsymbol{y}}^*, \boldsymbol{u}) \leq \zeta$. In this way hypotheses with a close to zero belief are set to zero so that they can be neglected in the next iteration, speeding up the "knockout race". This approximation can be mathematically described as

$$\mathbb{P}(i|\widehat{\boldsymbol{y}}^*, \boldsymbol{u}) \leftarrow \begin{cases} \mathbb{P}(i|\widehat{\boldsymbol{y}}^*, \boldsymbol{u})/\sum_{j \in I_\zeta} \mathbb{P}(j|\widehat{\boldsymbol{y}}^*, \boldsymbol{u}) & i \in I_\zeta \\ 0 & i \notin I_\zeta, \end{cases} \tag{7}$$

where $I_\zeta := \{j \in \mathbb{H} : \mathbb{P}(j|\widehat{\boldsymbol{y}}^*, \boldsymbol{u}) > \zeta\}$. We note that kernelization is not the only way to construct an expression for unavailable distributions. Another strong candidate would be the Approximate Bayesian Computation method, of which more information can be found in [23].

B. Input synthesis

This section focuses on synthesising a feasible input signal $\boldsymbol{u}$ at each time instant in order to generate an "optimal" measurement $\widehat{\boldsymbol{y}}^*$ for the Bayesian update described in (5). As a first step toward this goal we need to formally define such an optimal process. Intuitively speaking, a key feature

to isolate the fault modes is to separate the conditional distribution $\mathbb{P}(dy|i, \boldsymbol{u}) = p(y|i, \boldsymbol{u})dy$ from one another for all $i \in \mathbb{H}$. Note that in an ideal setting where these distributions have zero overlap, then in the posterior distribution update in (5), the quantity $p(\widehat{\boldsymbol{y}}^*|i, \boldsymbol{u}) = 0$ for all $i \neq i^*$. This means that the Bayes' rule (5) immediately converges to the optimal distribution fully supported on the true fault mode i^*. In this view, we first choose a distance function $D(\mathbb{P}_1, \mathbb{P}_2)$ that essentially captures the overlaps of two distributions $\mathbb{P}_1$ and $\mathbb{P}_2$, i.e., $\mathcal{D}(\mathbb{P}_1, \mathbb{P}_2) \geq 0$, and is zero if and only if $\mathbb{P}_1 \equiv \mathbb{P}_2$. Given this distance function, we then introduce the objective function

$$J(\boldsymbol{u}) := \sum_{i,j=1}^{n_K} \mathbb{P}(i)\mathcal{D}\Big(\mathbb{P}(dy|i, \boldsymbol{u}), \mathbb{P}(dy|j, \boldsymbol{u})\Big)\mathbb{P}(j). \quad (8)$$

Our goal is to maximize the objective function (8), and thus to reduce the similarity between the marginal distributions $\mathbb{P}(dy|i, \boldsymbol{u})$ for $i \in \mathbb{H}$, over the admissible set of inputs $\boldsymbol{u} \in \mathbb{U}$. The cumulative overlap between marginal distributions is weighted with the belief about their corresponding hypothesis candidates, such that the algorithm at any time focuses on separating the hypotheses with highest belief. From a computational perspective however, the function J in (8) may not be convex and it is not computationally feasible to solve $\max_{\boldsymbol{u} \in \mathbb{U}} J(\boldsymbol{u})$ per se. Therefore, we propose the projected gradient ascent update rule where at each iteration t, we only require to compute the gradient $\frac{\partial J}{\partial u}(u_t)$ at a given u_t. More formally, we propose

$$u_{t+1} = \Pi_{\mathbb{U}}\Big[u_t + \eta \frac{\partial J}{\partial u}(u_t)\Big] \qquad t \in \mathbb{N}, \quad (9)$$

where $\Pi_{\mathbb{U}}$ is the projected operation on the set $\mathbb{U}$, and the constant η is a prespecified stepsize. The key ingredient to implement the input update (9) is the computation of $\frac{\partial J}{\partial u}$, the gradient of the cost function. This quantity indeed entails the behavior of the algebraic equations (1). We note that the choice of the distant function $\mathcal{D}(\mathbb{P}_1, \mathbb{P}_2)$ is a degree of freedom as long as the basic properties of a metric on the space of distributions are fulfilled. In anticipation of the application in the next section and for numerical purposes, we consider the Hellinger distance defined as follows:

$$\mathcal{D}(\mathbb{P}_1, \mathbb{P}_2) = 1 - \int \sqrt{p_1(y)p_2(y)}dy. \quad (10)$$

The Hellinger distance (10) is qualified as a metric, as opposed to the common KL-divergence measure. This metric is also perceived as the stochastic analog of the Euclidean distance. The metric can therefore be implemented intuitively and unambiguously, because the three basic axioms (identity of indiscernibles, symmetry, and the triangle inequality) hold. Specifically, the symmetry axiom is important in this application, because the degree of overlap does not change with perspective between two overlapping spatial objects, i.e., $\mathcal{D}(\mathbb{P}_1, \mathbb{P}_2) = \mathcal{D}(\mathbb{P}_2, \mathbb{P}_1)$.

Proposition 1 (Cost function gradient). *Let the cost function $J(\cdot)$ be defined as in* (8) *where the distance function is* (10)*. Given $\boldsymbol{u} \in \mathbb{U}$ and realizations of random variables $\{\widehat{\boldsymbol{d}}_m, \widehat{K}_{i,m}\}$, $i \in I_\zeta$, let the set $\{\widehat{\boldsymbol{x}}(\boldsymbol{u})_m^{[i]}, \widehat{\boldsymbol{y}}(\boldsymbol{u})_m^{[i]} : i \in$*

Algorithm 1 Bayesian based active fault detection

Ensure: $t = 1$, $\mathbb{P}(i) = \mathbb{P}_0(i), \forall i \in \mathbb{H}$
1: **while** $\max_{i \in \mathbb{H}} \mathbb{P}(i) \leq p_{\max}$ **and** $t \leq t_{max}$ **do**
2:     Compute $\frac{\partial J}{\partial u}(u_{t-1})$ using (11)
3:     Update control u_t using (9)
4:     Measure real output $\tilde{\boldsymbol{y}}_t^*$
5:     **for** $i \in \mathbb{H}$ **do**
6:        Construct conditional distributions using (6)
7:        Sequentially update posterior distribution $\mathbb{P}(i|\widehat{y}_t^*, u_t)$ using (5) and (7)
8:     **end for**
9:     $t \leftarrow t + 1$
10: **end while**

I_ζ, $1 \leqslant m \leqslant M\}$ *be 'M' measurements of the model* (1)*. Suppose κ to be a kernel function and $\mathbb{P}(\boldsymbol{y}|\boldsymbol{u})$ is approximated by* (6)*. Then,*

$$\frac{\partial J}{\partial \boldsymbol{u}} = \frac{1}{2}\sum_{i,j} \mathbb{P}(i)\Big(\int \gamma_{i,j}(\boldsymbol{y}, \boldsymbol{u}) + \gamma_{j,i}(\boldsymbol{y}, \boldsymbol{u})d\boldsymbol{y}\Big)\mathbb{P}(j) , \quad (11)$$

where the function $\gamma_{i,j}$ is defined as

$$\gamma_{i,j} := \frac{\sum_{m=1}^M \kappa\big(\boldsymbol{y}, \widehat{\boldsymbol{y}}_m^{[i]}(\boldsymbol{u})\big)}{\sum_{m=1}^M \kappa\big(\boldsymbol{y}, \widehat{\boldsymbol{y}}_m^{[j]}(\boldsymbol{u})\big)}\Big(\frac{1}{M}\sum_{m=1}^M \frac{\partial \kappa}{\partial \widehat{\boldsymbol{y}}}(\boldsymbol{y}, \widehat{\boldsymbol{y}}_m^{[j]}(\boldsymbol{u}))\frac{\partial \widehat{\boldsymbol{y}}^{[j]}}{\partial \boldsymbol{u}}\Big),$$

$$\frac{\partial \widehat{\boldsymbol{y}}^{[j]}}{\partial \boldsymbol{u}} = \frac{\partial C}{\partial \boldsymbol{x}}\big(\frac{\partial F}{\partial \boldsymbol{x}}\big)^{-1}\frac{\partial F}{\partial \boldsymbol{u}}(\widehat{\boldsymbol{x}}_m^{[j]}(\boldsymbol{u}), \widehat{\boldsymbol{d}}_m, \boldsymbol{u}, \widehat{K}_{j,m}).$$

Proof: The proof comprises the following steps:
(i) Distance function gradient: Suppose $p_1(\boldsymbol{y}|\boldsymbol{u})$ and $p_2(\boldsymbol{y}|\boldsymbol{u})$ are two input-dependent density functions. Given distance function (10), we have by the chain rule

$$\frac{\partial}{\partial \boldsymbol{u}}\mathcal{D}\big(\mathbb{P}_1(\cdot), \mathbb{P}_2(\cdot)\big) =$$
$$-\frac{1}{2}\int \left(\sqrt{\frac{p_2(\cdot)}{p_1(\cdot)}}\frac{\partial p_1(\cdot)}{\partial \boldsymbol{u}} + \sqrt{\frac{p_1(\cdot)}{p_2(\cdot)}}\frac{\partial p_2(\cdot)}{\partial \boldsymbol{u}}\right)d\boldsymbol{y}.$$

(ii) Output perturbations: Suppose $\boldsymbol{y}(\boldsymbol{u})$ is the solution to (1). Then, given $(\boldsymbol{d}, K)$, we have

$$\frac{\partial \boldsymbol{y}}{\partial \boldsymbol{u}} = -\frac{\partial C(\boldsymbol{x})}{\partial \boldsymbol{x}}\left(\frac{\partial F}{\partial \boldsymbol{x}}\right)^{-1}\frac{\partial F}{\partial \boldsymbol{u}}.$$

Now the proof follows from the observations (i) and (ii), the description of the probability distribution (6) and (10). ∎

We close this section with Algorithm 1 summarizing the proposed Bayesian approach comprising two pivotal steps of the input synthesis (9) and the posterior update rule (5).

IV. Leakage localization in a WDN

In this section, the proposed methodology is further specified for the application to active leak localization in a WDN as described in Example 1. To this end, we first show how the mathematical model of WDNs fall into this category.

1) Model of a WDN: For the case of a WDN, the hypothesis candidates $\{1,\ldots,n_K\}$ correspond to possible leak locations at one of the n_K nodes. For a WDN at steady state, the equations describing the state $\boldsymbol{x} = \begin{bmatrix} \boldsymbol{q} & \boldsymbol{h} \end{bmatrix}^T$ of the network under leak mode i, can be represented by substitution of:

$$F^{[i]}(\boldsymbol{x}^{[i]}, \boldsymbol{u}, \boldsymbol{d}, K^{[i]}) : \begin{cases} E^{[i]}(\boldsymbol{x}^{[i]}, \boldsymbol{u}, \boldsymbol{d}, \boldsymbol{g}^{[i]}) = 0, \\ \boldsymbol{g}^{[i]} = L(\boldsymbol{x}^{[i]}; K^{[i]}), \end{cases},$$

in (1) we have

$$\text{Model}^{[i]} : \begin{cases} E^{[i]}(\boldsymbol{x}^{[i]}, \boldsymbol{u}, \boldsymbol{d}, \boldsymbol{g}^{[i]}) = 0, \\ \boldsymbol{g}^{[i]} = L(\boldsymbol{x}^{[i]}; K^{[i]}), \\ \boldsymbol{y}^{[i]} = C\boldsymbol{x}^{[i]}, \end{cases}, \quad (12)$$

where following [24] the term $E^{[i]}(\cdot)$ takes the form

$$E^{[i]}(\cdot) = \begin{bmatrix} A_{11}(\boldsymbol{q}^{[i]}) & A_{12} \\ A_{12}^T & 0 \end{bmatrix} \begin{bmatrix} \boldsymbol{q}^{[i]} \\ \boldsymbol{h}^{[i]} \end{bmatrix} + \begin{bmatrix} A_{10}\boldsymbol{u} \\ 0 \end{bmatrix} + \begin{bmatrix} 0 \\ -\boldsymbol{d} - \boldsymbol{g}^{[i]} \end{bmatrix} = 0 \quad (13)$$

with leak magnitude $\boldsymbol{g}^{[i]}$ in m^3/s being a function of the pressure $\boldsymbol{p}_i$ (part of the state vector $\boldsymbol{x}^{[i]}$) in mH_2O at the leak's location [25]. This yields

$$\boldsymbol{g}^{[i]} = L(\boldsymbol{x}^{[i]}; K^{[i]}) = K^{[i]}\boldsymbol{p}_i^\alpha, \quad \boldsymbol{p}_i = \rho_w g_c(\boldsymbol{h}_i - z_i). \quad (14)$$

The diagonal matrix $A_{11} \in \mathbb{R}^{n_p \times n_p}$ consists of the elements

$$A_{11}(j,j) = R_j|\boldsymbol{q}_j^{[i]}|^{\tau-1}, \quad j = 1,\ldots,n_p,$$

with R_j the resistance coefficient of pipe j; see [26] for further information. The matrices $A_{12} \in \mathbb{R}^{n_p \times n_n}$ and $A_{10} \in \mathbb{R}^{n_p \times n_u}$ are incidence matrices that denote the connectivity between the n_n unknown head nodes and the n_u nodes with regulated pressure heads $\boldsymbol{u} \in \mathcal{U}$, respectively. Using the Hazen-Williams (HW) energy loss model to describe the friction of pipes to flow, we have $\tau = 1.852$, $R_j = 10.670L_j/(C_j^{1.852}D_j^{4.871})$ where L_j, C_j, D_j denote the length in m, the unitless roughness coefficient and the diameter in m of pipe j, respectively [26]. The parameters describing the leak magnitude $(\rho_w, g_c, z_i, K_i, \alpha)$ denote the density of water in kg/m^3, gravity in m/s^2, elevation head z_i in mH_2O and the discharge constant $K_i > 0$ and $0 < \alpha < 1$ are parameters dependent on the leak size and pipe material. Finally, $\boldsymbol{y}^{[i]}$ denotes the measured part of state $\boldsymbol{x}^{[i]}$ with $C \in \mathbb{R}^{n_y \times n_x}$. With slight abuse of notation we use $C\boldsymbol{x}$ instead of $C(\boldsymbol{x})$, because in this specific application $\boldsymbol{y}$ is a linear combination of $\boldsymbol{x}$.

2) Specifications: Thanks to the WDN's model built above, the proposed methodology can now be applied for active leak localization in a real WDN as described by (12). What complicates the application is that in a real world setting the amount of leakage $\boldsymbol{g}$ is not known exactly. To mimic this situation, we therefore assume that only an estimate of $\boldsymbol{g}$ is available. For the M realizations needed to approximate the propagation of parametric uncertainties $(\boldsymbol{d}, \boldsymbol{g})$ into output distribution functions $\mathbb{P}(dy|i, \boldsymbol{u})$, $i \in \mathbb{H}$, it is assumed that the nodal demands are realizations $\hat{\boldsymbol{d}}_m$ from a Gaussian distribution $\hat{\mathbb{P}}_{\boldsymbol{d}}$. The availability of $\hat{\boldsymbol{g}}$ is mimicked by drawing

a realization from the uniform distribution $\boldsymbol{g} \sim \mathcal{U}_{\boldsymbol{g}}(\boldsymbol{g}^-, \boldsymbol{g}^+)$ centered at the actual leak magnitude $\boldsymbol{g}$, i.e., $\frac{\boldsymbol{g}^- + \boldsymbol{g}^+}{2} = \boldsymbol{g}$. Lastly, it is reasonably assumed that the parameters describing network characteristics like pipe diameter D_j and roughness coefficient C_j are calibrated using historical data and are time-invariant within fault detection time scales.

3) Input synthesis: Recall that synthesising a feasible input signal $\boldsymbol{u}$ using the gradient ascent update rule as proposed in equation (9) iteratively maximizes the cost function $J(\boldsymbol{u})$ in (8). The key ingredient is the computation of $\nabla_{\boldsymbol{u}}J(u_t)$ which entails the behavior of the WDN as described by (12). From Proposition 1 it follows that the only information needed to be able to compute (11) is to know how to compute $\nabla_{\boldsymbol{u}}\boldsymbol{y}$ and how to determine η.

Proposition 2 (WDN Cost function gradient). *Suppose that $\boldsymbol{y}^{[i]}(\boldsymbol{u})$ is a realization of* (12) *under fault mode i. Then, the sensitivity of a realization with respect to the input u is a matrix $\mathbb{R}^{n_u \times n_y}$ defined as*

$$\nabla_{\boldsymbol{u}}\boldsymbol{y}^{[i]} := \begin{bmatrix} \frac{\partial \boldsymbol{y}_1^{[i]}}{\partial \boldsymbol{u}_1} & \cdots & \frac{\partial \boldsymbol{y}_1^{[i]}}{\partial \boldsymbol{u}_{n_u}} \\ \vdots & \ddots & \vdots \\ \frac{\partial \boldsymbol{y}_{n_y}^{[i]}}{\partial \boldsymbol{u}_1} & \cdots & \frac{\partial \boldsymbol{y}_{n_y}^{[i]}}{\partial \boldsymbol{u}_{n_u}} \end{bmatrix} = \left(\nabla_{\boldsymbol{g}}\boldsymbol{y}^{[i]}\frac{\partial \boldsymbol{g}}{\partial \boldsymbol{h}_i}\right) \otimes \nabla_{\boldsymbol{u}}\boldsymbol{h}_i$$

$$= \bar{K}CS_{\boldsymbol{g}}^{[i]} \otimes S_{\boldsymbol{u}}^{[i]}[n_p + i]$$

where $\bar{K} = \frac{\partial \boldsymbol{g}}{\partial \boldsymbol{h}_i} > 0$, $S_{\boldsymbol{g}}^{[i]} \in \mathbb{R}^{n_x}$, and $S_{\boldsymbol{u}}^{[i]} \in \mathbb{R}^{n_x \times n_u}$ are the sensitivities of the state $\boldsymbol{x}$ with respect to leak magnitude $\boldsymbol{g}$ and to the inputs $\boldsymbol{u}$, respectively, i.e.,

$$S_{\boldsymbol{g}}^{[i]} := \begin{bmatrix} \frac{\partial \boldsymbol{q}}{\partial \boldsymbol{g}} & \frac{\partial \boldsymbol{h}}{\partial \boldsymbol{g}} \end{bmatrix}^{[i],T}, \quad S_{\boldsymbol{u}}^{[i]} := \begin{bmatrix} \nabla_{\boldsymbol{u}}\boldsymbol{q} & \nabla_{\boldsymbol{u}}\boldsymbol{h} \end{bmatrix}^{[i],T}. \quad (15)$$

Remark 1 (Measurement input-sensitivity). *Note that, due to the Kronecker product, the term $\nabla_{\boldsymbol{u}}\boldsymbol{h}_i$ does not affect the direction of $\nabla_{\boldsymbol{u}}\hat{\boldsymbol{y}}_j^{[i]}$ but only its magnitude, which corresponds with the intuition that changing inputs at different locations has a different impact on h_i.*

Proof: Application of the chain rule to a single element of $\nabla_{\boldsymbol{u}}\boldsymbol{y}^{[i]}$ yields: $\frac{\partial \boldsymbol{y}_j^{[i]}}{\partial \boldsymbol{u}_\nu} = \frac{\partial \boldsymbol{y}_j^{[i]}}{\partial \boldsymbol{g}}\frac{\partial \boldsymbol{g}}{\partial \boldsymbol{h}_i}\frac{\partial \boldsymbol{h}_i}{\partial \boldsymbol{u}_\nu}$, which comprises of the following parts:

(i)
$$\frac{\partial \boldsymbol{y}_j^{[i]}}{\partial \boldsymbol{g}} = CS_{\boldsymbol{g}}^{[i]}$$

(ii) As we assume an underlying leak model of the form in (14), this unidentifiable derivative can be elaborated as:

$$\bar{K} = \frac{\partial \boldsymbol{g}}{\partial \boldsymbol{h}_i} = \rho_w g_c \alpha K_i \left(\rho_w g_c(h_i - z_i)\right)^{\alpha-1} > 0$$

(iii)
$$\frac{\partial \boldsymbol{h}_i}{\partial \boldsymbol{u}_\nu} = S_{\boldsymbol{u}}^{[i]}[n_p + i; \nu]$$

Now the proof follows from (i), (ii) and (ii). ∎

4) Sensitivities: It is often claimed that the sensitivity matrix of the state with respect to leak magnitude $\boldsymbol{g}$ "is extremely difficult to calculate analytically" [11] because the non-linear hydraulic equations in (13) are implicit. In this paper the sensitivities are computed analytically by using the implicit function theorem, which reduces computational complexity and makes the proposed approach tractable. In the following proposition we address when the sensitivities required in equation (15) can be computed efficiently.

Proposition 3 (Analytical description of $S_{\boldsymbol{g}}^{[i]}$, $S_{\boldsymbol{u}}^{[i]}$). *Let $\boldsymbol{x}^*$ be a solution to algebraic equation* (13) *where the Jacobian $\partial F^{[i]}/\partial \boldsymbol{x}$ at $\boldsymbol{x}^*$ is invertible, i.e., the equation is non-degenerate. Then, the sensitivity matrices $S_{\boldsymbol{g}}^{[i]}$ and $S_{\boldsymbol{u}}^{[i]}$ in* (15) *can be calculated via*

$$\begin{bmatrix} S_{\boldsymbol{g}}^{[i]} & S_{\boldsymbol{u}}^{[i]} \end{bmatrix} = \begin{bmatrix} diag(\gamma_i)A_{11}(\hat{\boldsymbol{q}}^{[i]}) & A_{12} \\ A_{12}^T & 0 \end{bmatrix}^{-1} \begin{bmatrix} B_{\boldsymbol{g}}^{[i]} & B_{\boldsymbol{u}}^{[i]} \end{bmatrix}.$$

Proof: Since the function $F^{[i]}(\cdot)$ is continuously differentiable around such a solution $\boldsymbol{x}^*$ [24, Appx. 1], by the implicit function theorem [27, Thm. A.2], we have

$$\frac{\partial F^{[i]}(\cdot)}{\partial \boldsymbol{x}} \frac{\partial \boldsymbol{x}}{\partial \boldsymbol{g}} = -\frac{\partial F^{[i]}(\cdot)}{\partial \boldsymbol{g}}$$

$$\underbrace{\begin{bmatrix} \mathbb{N}_A A_{11}(\hat{\boldsymbol{q}}^{[i]}) & A_{12} \\ A_{12}^T & 0 \end{bmatrix}}_{A^{[i]}} \underbrace{\begin{bmatrix} \frac{\partial \boldsymbol{q}}{\partial \boldsymbol{g}} \\ \frac{\partial \boldsymbol{h}}{\partial \boldsymbol{g}} \end{bmatrix}^{[i]}}_{S_{\boldsymbol{g}}^{[i]}} = \underbrace{\begin{bmatrix} 0 \\ I^{[i]} \end{bmatrix}}_{B_{\boldsymbol{g}}^{[i]}}$$

where $\mathbb{N}_A = diag(\gamma_i)$, $i = 1, \ldots, n_p$ and the only nonzero element of vector $I^{[i]} \in \mathbb{R}^{n_n}$ is $I^{[i]}(i) = 1$. Therefore, sensitivity $S_{\boldsymbol{g}}^{[i]}$ can be computed by solving the n_x linear equations, i.e., $S_{\boldsymbol{g}}^{[i]} = A^{[i]} \backslash B_{\boldsymbol{g}}^{[i]}$.

Likewise, at the same steady state solution $\boldsymbol{x}^*$ we can write:

$$\frac{\partial F^{[i]}(\cdot)}{\partial \boldsymbol{x}} \nabla_{\boldsymbol{u}} x = -\nabla_{\boldsymbol{u}} F^{[i]}(\cdot)$$
$$A^{[i]} S_{\boldsymbol{u}}^{[i]} = B_{\boldsymbol{u}}^{[i]},$$

where $B_{\boldsymbol{u}}^{[i]} = \begin{bmatrix} A_{10} \\ 0 \end{bmatrix}$ and we obtain $S_{\boldsymbol{u}}^{[i]} = A^{[i]} \backslash B_{\boldsymbol{u}}^{[i]}$. ∎

Remark 2 (Computational complexity). *The complexity of the proposed algorithm is determined by solving $n_n \times n_x \times (M + 1 + n_u)$ linear algebraic equations where n_n is the number of unknown nodes, n_x is the number of the states including all the flows and hydraulic heads, n_u is the number of inlets, and M is the number of realizations.*

V. CASE STUDY

In this section, the proposed AFD method is numerically evaluated by comparing to a PFD method under different levels of demand uncertainty. It is assumed that no prior information is available about where approximately the leak is located, such that the initial belief is a uniform distribution over the nodes.

A. Hanoi Network

In order to assess Algorithm 1, its performance is tested on the benchmark Hanoi network [28] and compared against the state-of-the-art PFD method introduced in [13] with the slight difference that the output space is directly used here. This is implemented by using Algorithm 1 without the active control rules, i.e. lines 2 and 3 are skipped. Figure 1 shows a schematic representation of this network, which is fed by two reservoirs. This trunk model consists of 31 nodes connected by 33 pipes. At nodes 14, 22 and 30, pressure loggers are installed. The pressures at nodes 1 and 9 are controlled by means of PRVs, which will be referred to as inputs $\boldsymbol{u}_1$ and $\boldsymbol{u}_2$, respectively. To demonstrate the algorithm's ability to handle multiple inputs, the default Hanoi network from [28] is extended with an extra reservoir and PRV at node 9. The WDN contains two trees (i.e. acyclic, connected subgraphs of the network): 9-10-11-12 and 19-20-21. Leaks at these nodes of equal magnitude affect the pressure distribution across the looped part of the network identically and are therefore not isolable. Therefore, as is done in model reduction for WDNs [29], the nodes in these trees are grouped into corresponding sets and are represented by the root node of the tree - nodes 9 and 19, respectively. This prevents the algorithm from getting stuck in an attempt to isolate non-isolable leaks.

The size of each time step during fault diagnosis is in the order of minutes, such that steady state can be considered and dynamic sub-second processes can be neglected.
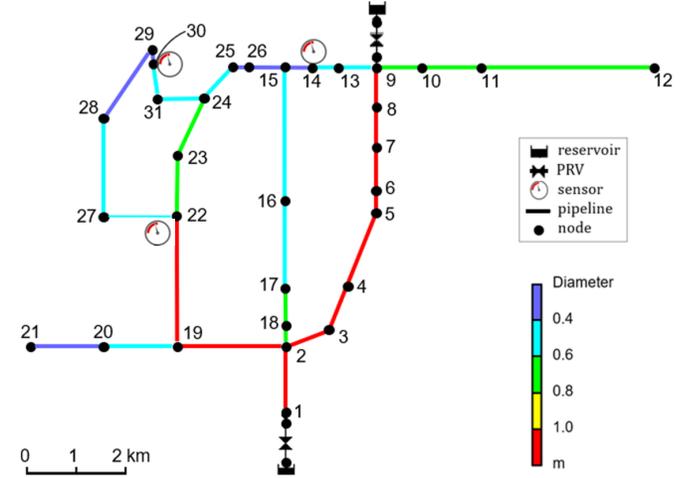

Fig. 1: The benchmark Hanoi trunk network.

B. Simulation Setup

Since the real Hanoi network is not available to validate the proposed AFD algorithm, we resort to simulating the hydraulics described via (1) for numerical purposes. To this end, a single leak scenario is investigated where the node i^* is the location of the leak whose level of the leakage is described by (14). In this setting, the leak parameters used in the simulation experiments are listed in Table I.

The obtained model M_{i^*} is used as if it were the real Hanoi network. Figure 2 shows a schematic representation of how

TABLE I: Leak model characteristics

K	α	$\rho_w [kg/m^3]$	$g_c [m/s^2]$
0.0005	0.75	0.5	9.81

inputs and outputs of the 'real' network are imitated and how these interact with the AFD method. The consumer demands $\hat{d}_t$ projected at the nodes of the 'real' (M_{i*}) network are determined by:

$$d_{k,j} = \max(\boldsymbol{\xi}_d, 0)\mu_t b_j, \ \forall j \in \mathcal{I}_n \tag{16}$$

where b_j is the base demand of the jth node, μ_t is the demand multiplier at time step t and $\boldsymbol{\xi}_d$ is randomly drawn from normal distribution $\boldsymbol{\xi_d} \sim \mathcal{N}(1, \sigma_d)$ [30].
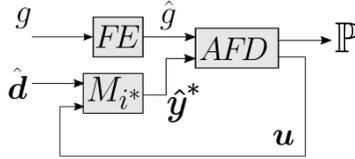

Fig. 2: Schematic representation of the simulation setup to mimic a real implementation of the AFD algorithm on the Hanoi water distribution network for a single time step.

The output at each time step is generated by solving the non-linear hydraulic equation of M_{i*} and obtaining its output $\tilde{\boldsymbol{y}}_t$. The FE (Fault Estimation) block in Figure 2 models the magnitude estimation of leak $\boldsymbol{g}$ and predicts its value according to $\hat{\boldsymbol{g}}_t = \boldsymbol{g}_t + \boldsymbol{\xi}_g$ where $\boldsymbol{\xi_g} \sim \mathcal{N}(0, \sigma_g)$. The AFD block takes as input the estimated leak magnitude $\hat{\boldsymbol{g}}_t$ and the output observation $\tilde{\boldsymbol{y}}_t$ and based on these updates the input $\boldsymbol{u}_t$ and likelihood vector $\mathbb{P}_t$. Within the AFD block the leak magnitude PDF $\mathbb{P}_{\boldsymbol{g}}$ and output PDF $\mathbb{P}_{\boldsymbol{y}}$ are estimated at each time step t and used for execution of algorithm 1. The leak magnitude PDF is assumed to be uniformly distributed around the estimated leak magnitude, i.e., $\boldsymbol{g} \sim \mathcal{U}(\hat{\boldsymbol{g}} - 3\sigma_{\boldsymbol{g}}, \hat{\boldsymbol{g}} + 3\sigma_{\boldsymbol{g}})$. The output PDF is estimated as described in section IV. For this setup a Gaussian kernel was used with bandwidth determination based on Scott's rule, [31]. The control inputs have the upper bound $\boldsymbol{u}_{max}$ and are lower bounded by the required minimal service level pressure head of $15\ m$ at the critical point, node 30 in this case being the node in the lowest pressure area of the network [9]. In any case the pressure at this critical point needs to be maintained above its critical level. Therefore, dependent on the scenario, the inlet pressure heads $\boldsymbol{u}_1$ and $\boldsymbol{u}_2$ have a different lower bound per steady state. This is the reason that the inputs in Figure 3b (passive method) are not straight lines. Furthermore, a constraint $\Delta_{\boldsymbol{u},max}$ is imposed on the input change rate due to the PRV's characteristics. The leak magnitude is bounded by about $[0.02, 0.05]\ m^3/s \Leftrightarrow [1.0, 2.5\%]$ of the mean total demand between 0AM and 5AM. All necessary simulation constants are specified in Table II. Since the amount of computing power required to perform the simulations depends on M, its value has has been minimized. Lower values for M make that the PDF estimates are filled with gaps, such that the actual output space is not covered. Likewise the stepsize η is a design parameter and has been optimized in such a fashion

that the gradient in (9) controls $\Delta_{\boldsymbol{u}} = \eta \frac{\partial J}{\partial u}$. Taking a too large η makes that always $\Delta_{\boldsymbol{u}} = \Delta_{\boldsymbol{u},max}$, such that the gradient is in fact out of play. On the other hand when η goes to zero, the active algorithm becomes passive. The simulation experiments

TABLE II: Simulation constants

M	ζ	$\boldsymbol{u}_{max}[mH_2O]$	$p_{\max}$
80	$5/10^4$	100	0.95
$\Delta_{\boldsymbol{u},max}[mH_2O]$	η	$\sigma_{\boldsymbol{g}}[m^3/s]$	t_{max}
5	50	0.003	60

were performed using the WNTR Python package [32] and its built-in hydraulic solver.

C. Experiments and Scenarios

The following numerical experiments are set up and performed 5 times for scenarios with different nodal demand realizations:

(i) i^* is varied over all 26 considered leak locations, i.e. all classes of nodes where trees are aggregated into corresponding root nodes. The AFD algorithm is directly compared to its PFD counterpart. The two algorithms have identical initial conditions and are activated during nighttime between 0AM and 5AM with a time step of 5 minutes. The algorithms try to isolate the leak location within this time frame.

(ii) Step (i) is repeated for 2 different values of the demand distribution variance σ_d, namely: $\sigma_d \in [0.01, 0.10]$.

To measure the performance of the AFD and PFD methods, *accuracy* and *average distance* are used as metrics. Accuracy is measured by the percentage of leaks that are classified to the correct leak location within the time frame of 0AM and 5AM. The average distance is the mean distance in kilometers between the 'as classified' and actual leak location i^*, calculated with Dijkstra's algorithm [33].

Remark 3. *The experiments simulate fault diagnosis at nighttime, because the ratio between leakage and total inflow at the inlets is the largest in these hours [34]. Nodal consumer demands are more predictable as well, i.e. have a lower variance, such that leaks to a lesser extend are getting obscured by the increased uncertainty imposed by a higher variance. [21].*

D. Results

Figures 3a and 3b show the input and likelihood trajectories resulting from a single AFD and PFD diagnosis with a leak at node 1, i.e $i^* = 1$, and demand distribution variance $\sigma_{\boldsymbol{d}} = 0.10$. Figures 4a and 4b show similar trajectories for a leak at node 6, i.e. $i^* = 6$, under equal conditions. The spatial distribution of the nodes is shown in Figure 1. All scenarios are equally initiated regarding demands and leak magnitude estimation.

In both cases ($i^* = 1$, $i^* = 6$) the AFD trajectories can be roughly divided into two periods: 1) leak area selection and 2) isolation of the most likely leak node or location, described below.

1) The pressures in the network are low and many hypotheses are initially posed. The algorithm aims to fan out
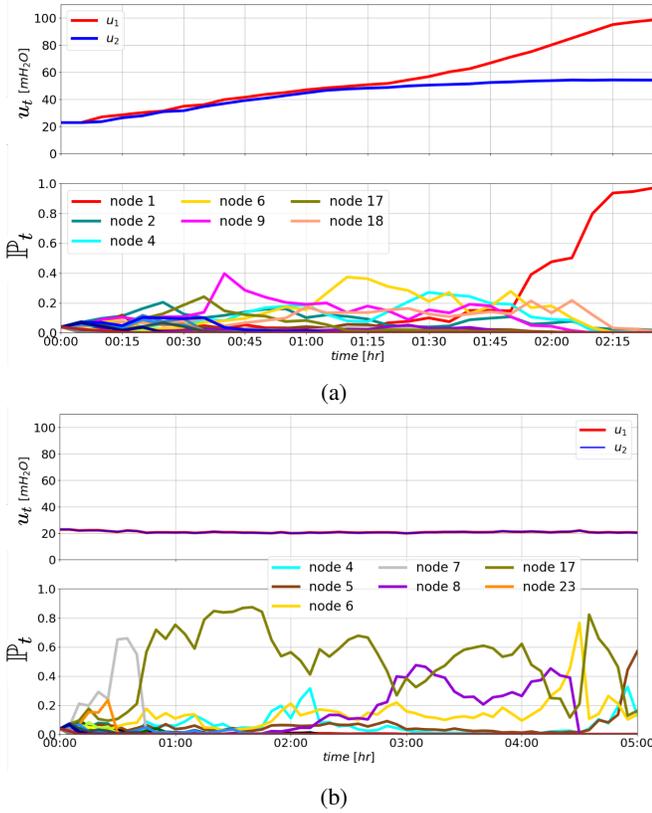

Fig. 3: Input and likelihood trajectories for a single experiment with initially equal scenarios resulting from (a) AFD and (b) PFD diagnosis ($i^* = 1$).

Fig. 4: Input and likelihood trajectories for a single experiment with initially equal scenarios resulting from (a) AFD and (b) PFD diagnosis($i^* = 6$).

all the corresponding densely packed output PDFs by increasing the control inputs, sometimes at the maximum allowed rate. In this way it aims to stepwise maximize the objective function $J(\cdot)$ in (8).

2) In this period, many hypotheses have been rejected based on a sequence of output measurements and the algorithm focuses on separating the output PDFs of the remaining hypotheses. It is observed that the inputs diverge due to their different effect on separating the remaining output PDFs, i.e., $\frac{\partial J}{\partial \boldsymbol{u}_1}$ and $\frac{\partial J}{\partial \boldsymbol{u}_2}$ diverge from each other. As the likelihood vector $\mathbb{P}_t$ changes over time (line 7 in Algorithm 1), the varying dominant hypotheses determine the stagnation or increase of the different inputs. This clearly demonstrates the adaptive behavior of the AFD algorithm, which determines the input directions based on the 'current belief'. When the hypotheses of two spatially closely related nodes have both a high likelihood, it is observed that the inputs tend to grow faster due to the relative high overlap between their output PDFs. It can be observed that, as a rule of thumb, when output PDFs of the most likely hypotheses at a certain time step have little overlap, the inputs stagnate. In contrast, when the dominant hypotheses are have a high overlap of output PDFs in the full output space, the input vector takes a step in the direction in which maximum separation of the output PDFs corresponding with the dominant hypotheses
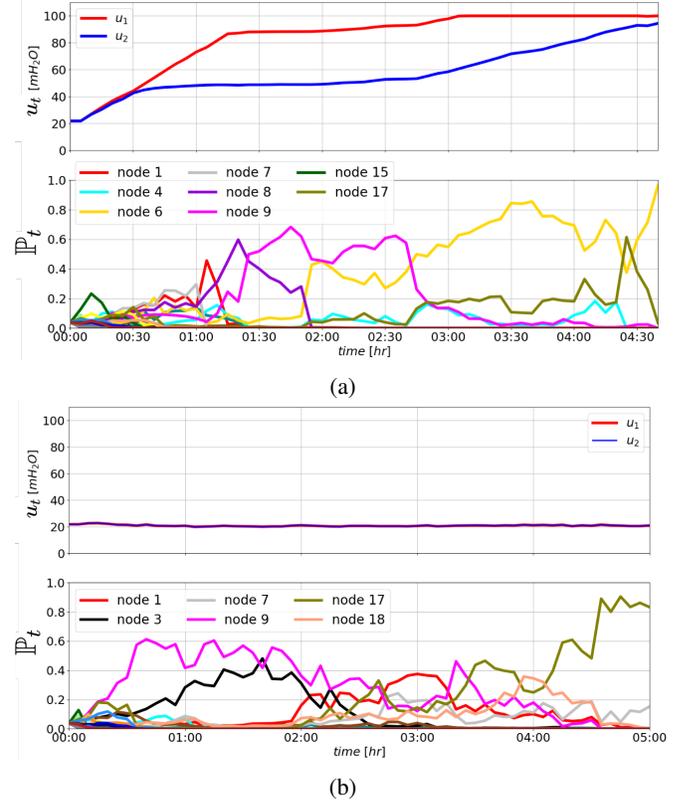

is expected, that is, maximising J with respect to $\boldsymbol{u}$.

Comparing the trajectories of $\mathbb{P}_t$ between the PFD and AFD in these two experiments shows that the PFD method has a poorer performance in terms of speed, accuracy and decisiveness. The different hypotheses struggle for precedence, but their corresponding output PDFs clearly have too much overlap which makes that the PFD algorithm comes no further than region selection. Of course this does not mean that the AFD algorithm is superior in every experiment. Both algorithms are heavily dependent on the 'separating quality' of observed outputs at each time step. To show that the AFD algorithm has an overall better performance than its PFD counterpart, in Figure 5 the accuracy and average distance time-lapse trajectories over all 130 scenarios (26 experiments repeated with 5 demand realizations) are plotted for the two different levels of demand uncertainty (different values of $\sigma_{\boldsymbol{d}}$).

The upper plot shows how the accuracy evolves over diagnosis time for different values of demand distribution variance $\sigma_{\boldsymbol{d}}$. Likewise the lower plot shows the development over time for the average 'distance to actual leak' performance metric in kilometers. Compared to the PFD algorithm, the accuracy of the AFD algorithm is higher by 12 and 9 per cent for the demand variance values of 0.01 and 0.1, respectively. Similarly, the average distance is lower for the AFD by, respectively, 0.37 and 0.75 kilometers. Finally, the mean diagnosis time for the AFD are 117 and 164 minutes, whereas the PFD takes 45
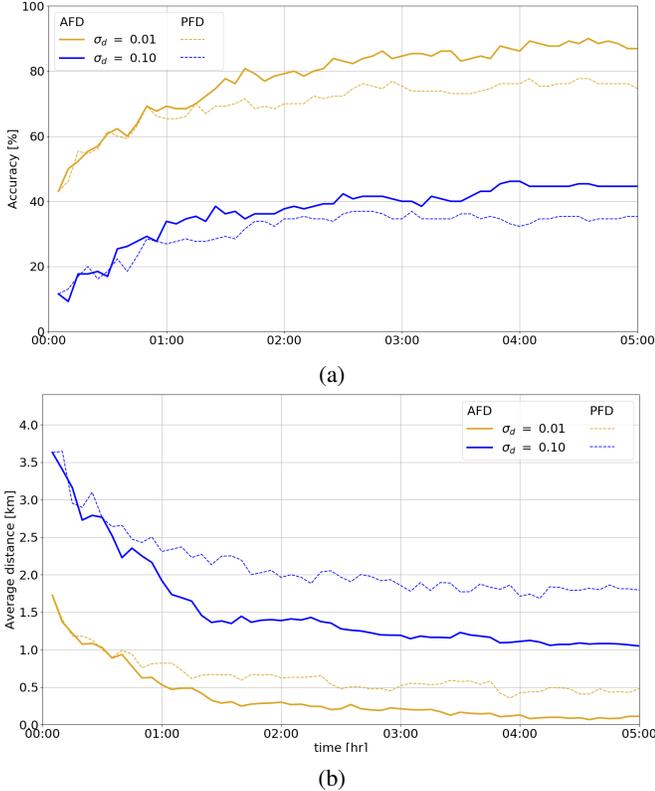

Fig. 5: Performance of AFD and PFD methods over a 5 hour diagnosis period. The performance measures are averaged over all experiments, where leaks are placed at different nodes in each experiment. Two scenarios with different levels of demand uncertainty are considered. (a) accuracy in finding exact leak nodes [%] and (b) average distance of nodes classified as leak location to actual leak nodes [km].

TABLE III: Results sensitivity-analysis of parameter M

M	10	20	40	60	80	100	120
Accuracy [%]	27	13	7	11	31	15	25
Average distance [km]	2.2	1.7	1.4	1.0	1.1	1.2	1.1
$\mathrm{Var}_{\text{distance}}$ [km]	2.0	1.3	0.9	0.7	0.9	0.6	0.6

and 50 minutes longer, respectively.

E. Robustness of the proposed AFD algorithm

Algorithm 1 depends on a number of parameter choices as inputs, whose values are presented in Table II. Some of these are hyperparameters as their value controls the Bayesian learning process of the algorithm. Here we investigate the sensitivity of the AFD's performance to some of these parameter choices.

Hyperparameter M: The parameter M denotes the number of realizations sampled to construct Probability Density Functions corresponding to the different hypotheses as in Equation (6). As such it affects how well we estimate the output distributions at each iteration, and therefore overall performance of the algorithm. We performed closed-loop simulations of our AFD algorithm for hyperparameter M; for each M in $\{10, 20, 40, 60, 80, 100, 120\}$ the algorithm's performance was tested using different performance metrics.

Table III shows performance for the diagnosis with respect to M, while the other parameters in Table II were fixed. As an example, a leak at node 3 is simulated and the algorithm is tested with 15 closed-loop experiments to assess its average performance and variances in performance; 15 experiments were found, a posteriori, to be sufficient to show convergence in these performance metrics shown in Table III.

From this example analysis in Table III, we can observe the following regarding the sensitivity of performance to M:

- The Average Distance between the node classified as leaky and the actual leaky node i^* drops with increasing M. After $M \geqslant 60$ it stagnates at $\sim 1km$ distance for this network example. The variance $\mathrm{Var}_{\text{distance}}$ of this metric also saturates beyond $M = 80$.
- When M is increased, the algorithms takes more iterations to reject hypotheses, because the overlap of output PDFs increases with M. The result is that the algorithm converges slower with increasing M.
- When M is small (eg. $M = 10$), the algorithm converges very fast and its results can therefore be qualified as quick guesses with outliers far outside the neighborhood of i^*.
- M largely affects the computation speed because the water distribution network needs to be simulated M times, at each iteration of the AFD algorithm and for each hypothesis with nonzero belief. However, it is also important to emphasize that these network simulations between hypothesis and control updates are fully parallelisable (the for loop in lines 5-8 of Algorithm 1); network simulations can be done in parallel across the different hypotheses with nonzero belief and across the M samples made for each hypothesis.

From similar simulations over many leaks, we can conclude that the proposed AFD algorithm was found to be robust to this hyperparameter values since a sufficiently large M value could be found to ascertain good performance in terms of distance to actual leak and with low variance of this performance. For the network example in this manuscript, and as also depicted in Table III, $M = 80$ (the value selected for the experiments in Table II) gives a good trade-off between computational burden and performance.

Other (hyper)parameters:

As shown in Figure 5, impact of the uncertainty of nodal demands σ_d, has a big impact on the performance of the algorithm as it accounts for the uncertainty within the system under normal operations, even without a leak. Unlike for M, σ_d has little impact on the algorithm convergence rate but rather does affect its ability to find the accurate leak location or proximity to it. As diurnal demand uncertainty becomes larger, the impact of a leak on the measured output variable $\widehat{\boldsymbol{y}}^*$ falls within normal operations and therefore its identification becomes less accurate, and less precise in distance to actual leak.

Other parameters in Table II did not affect the algorithm performance, or were controlled design or system parameters. These are:

- ζ: this hyperparameter can always be set sufficiently close to zero and could be controlled to have no influence on

the algorithm's performance. It has an influence on the computational speed, since hypotheses that have a belief lower than $zeta$ get set to zero, after which the belief vector is renormalized. This is because at each iteration, the algorithm has to construct the PDF's of all unrejected hypotheses. However, this burden is fully parallelisable and so can be mitigated with parallel computational resources.

- $\mathbf{u}_{max}$: this parameter comes from regulatory constraints on system pressure only sets a maximum on the input vector, such that the pressure in a physical water distribution network does not exceed its maximum allowable pressure.
- p_{max}: this parameter is used as a stopping criterion, whenever the belief of a single hypothesis exceeds p_{max}, set to 0.95 here, the algorithm terminates and qualifies that node to be the leaky one.
- $\Delta_{\mathbf{u},max}$: this parameter limits the stepsize in u in a single control time step. This often comes from pressure control valve operation constraints.
- η: this hyperparameter determines how active the algorithm is. When chosen close to zero it the active algorithm converges to its passive counterpart. So it does not directly make the algorithm robust but rather controls it to be more or less active.
- σ_g: this is a design parameter for the experiments;
- t_{max}: this is a design parameter for the experiments.

VI. CONCLUSION & FUTURE DIRECTIONS

A tractable active fault isolation method is proposed for a class of non-linear models subject to faults and applied to locate leaks in a WDN with uncertain user demands and unknown leak magnitude. The method relies on the classification of output observations to a discrete set of hypotheses. The uncertainties are captured by output PDFs which are used to iteratively update the posterior probability of each hypothesis in a Bayesian framework. The AFD algorithm proactively minimizes the joint overlap between output PDFs by designing optimal control inputs. A new numerically scalable approach for synthesising such control inputs on the fly is derived. The performance is tested for two levels of demand uncertainty and compared to the PFD counterpart method. Improvements of the performance metrics accuracy and average distance as well as diagnosis speed are observed. It can be concluded that the AFD method is more reliable and faster compared to its state-of-the-art PFD counterpart. It is further shown that the AFD algorithm updates the inputs in an economical way, i.e., the inputs are only adjusted when this is in favor of the objective. The robustness of the AFD algorithm was also tested, showing that hyperparameter values could be selected appropriately to guarantee good performance. The number of output realisations of the system, sampled to estimate the output Probability Density Functions corresponding to the different hypotheses, was shown as main hyperparameter that affects performance and computational burden. We note that the number of system simulations required at each iteration, which grows linearly with number of realisations sampled and number of hypothesis not yet rejected, is fully parallelisable and may not be burdensome even for large number of realisations sampled. Future follow-up studies are encouraged to study optimal sensor and input placement to facilitate AFD.
